CSE 4/587 — End-to-End Big Data Pipeline

Phase 2 Report

Project: Stock Movement Prediction Using S&P 500 Historical Data

Dataset: S&P 500 Stock Prices 2014–2017

Repo: https://github.com/stubdude/cse587-phase1-merged

Team:

Name	UBIT	Email
Harshvardhan Shinde	hdshinde	hdshinde@buffalo.edu

Date: April 25, 2026

In Phase 2 we pick up from the cleaned dataset we stored in HDFS during Phase 1 (497,460 rows, 16 columns). We train three ML models with PySpark MLlib and work through the six data analysis objectives we proposed earlier.

Task 1 — Spark ML (50 pts)

We implement 3 ML algorithms in PySpark to tackle the 3 problems from Phase 1:

#	Problem	Algorithm	Metrics
1	Classification — up or down?	Random Forest	Accuracy, F1, AUC-ROC
2	Regression — predict daily return	GBT	RMSE, MAE, R^2
3	Clustering — group similar stocks	K-Means	Silhouette Score

Feature Engineering

Before training models, we create lagged features so that predictions only use information available *before* the trading day we're predicting. Specifically:

1. **Lagged daily return** — previous day's percentage return
2. **Lagged price range** — previous day's high minus low
3. **Lagged log-volume** — previous day's log-transformed volume
4. **Previous close** — yesterday's closing price (proxy for today's price level)
5. **Binary label** for classification: 1 if the stock went up (daily_return > 0), 0 otherwise

We also drop the first row per stock since it has no lag available.

In [3]:
```
w = Window.partitionBy("symbol").orderBy("date")

df = df.withColumn("prev_daily_return", F.lag("daily_return", 1).over(w))
df = df.withColumn("prev_price_range", F.lag("price_range", 1).over(w))
df = df.withColumn("prev_log_volume", F.lag("log_volume", 1).over(w))
df = df.withColumn("prev_close", F.lag("close", 1).over(w))

# Binary label: 1 if stock went up, 0 if down/flat
df = df.withColumn("label", F.when(F.col("daily_return") > 0, 1.0).otherwise

# Drop rows where lag is null (first trading day per stock)
df = df.na.drop(subset=["prev_daily_return", "prev_price_range", "prev_log_v

print(f"Dataset after feature engineering: {df.count():,} rows")
print()
print("Label distribution (classification target):")
df.groupBy("label").count().orderBy("label").show()
```

```
Dataset after feature engineering: 496,955 rows

Label distribution (classification target):
+-----+------+
|label| count|
+-----+------+
|  0.0|241282|
|  1.0|255673|
+-----+------+
```

In [4]:
```
train_df, test_df = df.randomSplit([0.8, 0.2], seed=42)
print(f"Training set: {train_df.count():,} rows")
print(f"Test set:     {test_df.count():,} rows")
```

```
Training set: 397,788 rows
Test set:     99,167 rows
```

Problem 1: Classification — Predict Stock Direction

Goal: Given yesterday's trading data for a stock, predict whether today's close will be higher than today's open (i.e., will the stock go up or down?).

Why Random Forest?

Our Phase 1 EDA showed that daily returns have fat tails (kurtosis ~1.1) and are not normally distributed. Tree-based models make no distributional assumptions, so they handle this naturally. Random Forest specifically:

- Builds many independent decision trees on random subsets of data and features, then takes a majority vote. This reduces overfitting compared to a single tree.
- Handles the mix of numeric features and categorical features (like sector) without requiring feature scaling.
- Gives us feature importance scores, so we can see which inputs actually help predict stock direction.

We considered Logistic Regression as a baseline but went with RF directly since the EDA correlation heatmap showed that feature-target relationships are likely nonlinear.

Features: prev_daily_return, prev_price_range, prev_log_volume, prev_close, sector (one-hot encoded), day_of_week, month

Metrics: Accuracy, F1-score (weighted), AUC-ROC

In [5]:
```
# --- Pipeline components ---
sector_indexer = StringIndexer(inputCol="sector", outputCol="sector_idx", ha
sector_encoder = OneHotEncoder(inputCol="sector_idx", outputCol="sector_vec"

clf_feature_cols = [
    "prev_daily_return", "prev_price_range", "prev_log_volume",
    "prev_close", "day_of_week", "month"
]
assembler_clf = VectorAssembler(
    inputCols=clf_feature_cols + ["sector_vec"],
    outputCol="features"
)

rf = RandomForestClassifier(
    featuresCol="features", labelCol="label",
    seed=42
)

pipeline_clf = Pipeline(stages=[sector_indexer, sector_encoder, assembler_cl

# --- Evaluators ---
acc_eval = MulticlassClassificationEvaluator(
    labelCol="label", predictionCol="prediction", metricName="accuracy"
)
f1_eval = MulticlassClassificationEvaluator(
    labelCol="label", predictionCol="prediction", metricName="f1"
)
auc_eval = BinaryClassificationEvaluator(
```

```
    labelCol="label", rawPredictionCol="rawPrediction", metricName="areaUnde
)
```

Classification Results Discussion

The Random Forest achieves accuracy slightly above 50%, which is only marginally better than a coin flip. This is actually a well-known result in finance: daily stock direction is extremely hard to predict from historical price data alone. The efficient market hypothesis argues that all publicly available information is already priced in, leaving returns essentially random on a day-to-day basis.

What the metrics tell us:

- The accuracy hovering around 50-53% shows the model picks up a weak signal but nothing strong enough for reliable trading.
- The AUC-ROC above 0.5 confirms there's *some* predictive information in the features, but the discrimination between up and down days is poor.
- The F1-score reflects the balance (or imbalance) between precision and recall for both classes.

Feature importance:

- `prev_daily_return` (yesterday's return) is the most important feature, consistent with short-term momentum/mean-reversion effects that have been documented in finance literature.
- `prev_close` (price level) matters because different price ranges have different volatility characteristics.
- `sector` contributes as well, confirming our Phase 1 finding that sectors have different return profiles.

Hyperparameter tuning:

- We searched over 4 combinations of numTrees and maxDepth using 3-fold cross-validation on a 20% data sample to manage memory limits.
- The improvement from tuning was marginal, which suggests the bottleneck is the feature set (signal-to-noise ratio in the data), not the model's capacity.

Problem 2: Regression — Predict Daily Percentage Return

Goal: Predict the actual daily return (close - open) / open * 100 for a stock on a given day, using the previous day's features.

Why Gradient-Boosted Trees (GBT)?

GBT builds trees sequentially, where each new tree corrects the errors made by the previous ones. This is different from Random Forest where trees are independent:

- GBT is well-suited for regression tasks where the relationship between features and target is nonlinear. Our Phase 1 correlation analysis showed weak linear correlations between features and returns, so a model that captures nonlinear patterns should do better than plain linear regression.
- The sequential correction mechanism lets GBT focus on hard-to-predict samples, which is useful since stock returns have heavy tails and outliers.
- GBT with shallow trees (low maxDepth) acts as a strong regularizer, preventing overfitting to noise in the training data.

We chose GBT over Linear Regression (which assumes linearity) and SVR (which is computationally expensive at this scale).

Features: prev_daily_return, prev_price_range, prev_log_volume, prev_close, sector (one-hot encoded), day_of_week, month

Target: daily_return (continuous, in %)

Metrics: RMSE, MAE, R^2

In [8]:

        Predict train mean 1.218996 0.902960                    1.000000
Predict test mean (oracle) 1.218987      NaN                    0.999993
               GBT (tuned) 1.209080 0.895143                    0.991866

GBT R²:                              0.016189
GBT skill score vs train-mean:       +0.008134
GBT skill score vs predict-zero:     +0.008367

-> GBT beats the train-mean baseline by 0.813% RMSE reduction.
```

Regression Results Discussion

Performance overview:

- The RMSE of ~1.2% means the model's predictions are typically off by about 1.2 percentage points. Given that the standard deviation of daily returns in our dataset is also about 1.2%, the model is essentially predicting close to the mean.
- The R^2 value near zero (or slightly negative) means the model explains very little of the variance in daily returns. This is consistent with what we see in the scatter plot: predictions cluster tightly around zero while actual returns spread widely.

- The baseline-comparison table makes this explicit: the GBT's RMSE is essentially the same as the "always predict the train mean" and "always predict 0" baselines. The skill score (`1 - RMSE_model / RMSE_baseline`) is within noise of zero, confirming the model is not meaningfully better than a constant predictor on unseen data.

Why is this hard?

Daily stock returns have an extremely low signal-to-noise ratio. The "signal" (predictable component from yesterday's features) is tiny compared to the "noise" (everything else that moves stocks: news, earnings, macro events, etc.). This is well-established in finance research. The model isn't broken; the problem is genuinely difficult.

Residual analysis:

- The residuals are roughly centered at zero with approximately symmetric distribution, which means the model isn't systematically biased.
- The heavy tails in the residuals reflect the fat-tailed nature of stock returns we identified in Phase 1.

Hyperparameter tuning:

- Tuning maxDepth and maxIter yielded only marginal RMSE improvements. Shallower trees (lower maxDepth) tend to generalize slightly better, confirming that overfitting is a risk with noisy financial data.

Problem 3: Clustering — Group Stocks by Trading Behavior

Goal: Find natural groupings among stocks based on their aggregate trading characteristics (average return, volatility, volume, price range), and see whether these clusters align with sector labels.

Why K-Means?

K-Means is the standard algorithm for partitioning data into K groups based on distance to cluster centroids:

- It scales well to our dataset size and is available in Spark MLlib.
- The algorithm is straightforward to interpret: each stock belongs to the cluster whose centroid is closest.
- We standardize features before clustering since K-Means uses Euclidean distance, and our features are on very different scales (volume is in the millions, returns are single-digit percentages).

We evaluate different values of K (2 through 10) using the silhouette score to find the optimal number of clusters. The silhouette score measures how similar each point is to its own cluster compared to other clusters, ranging from -1 (wrong cluster) to +1 (well-clustered).

Features (per stock): mean_return, volatility (std of daily returns), avg_log_volume, avg_price_range

In [12]:
```
# Aggregate trading statistics per stock
stock_features = df.groupBy("symbol", "sector").agg(
    F.mean("daily_return").alias("mean_return"),
    F.stddev("daily_return").alias("volatility"),
    F.mean("log_volume").alias("avg_log_volume"),
    F.mean("price_range").alias("avg_price_range")
).na.drop()

print(f"Number of stocks for clustering: {stock_features.count()}")
stock_features.describe().show()
stock_features.show(10, truncate=False)
```

```
Number of stocks for clustering: 505

Clustering Results Discussion

Silhouette analysis:

- We tried K values from 2 to 10. The silhouette scores help determine how many natural groupings exist in the stock data.
- Silhouette peaks at K=2, which is why K=2 is selected. The elbow plot does not show a sharp bend at K=2; inertia keeps falling smoothly until roughly K=5–6. We prioritize the silhouette criterion here because it directly measures cluster separation/cohesion, while the elbow is only a visual heuristic. A larger K (e.g., 4–5) gives finer-grained groupings but lower average separation.

Cluster interpretation:

- The scatter plots show how stocks separate along the return-volatility and volume-price range dimensions.
- Some clusters clearly correspond to high-volatility stocks vs. low-volatility stocks, which makes financial sense since risk and return are related.
- The volume dimension separates heavily traded large-cap stocks from less liquid mid/small-cap stocks.

Cluster-sector alignment:

- The heatmap shows that clusters do partially align with sectors. For example, Utilities and Consumer Staples (traditionally low-volatility "defensive" sectors) tend to cluster together, while Energy and some Tech stocks (higher volatility) group separately.
- However, the alignment is not perfect, which is actually the interesting finding: some stocks in traditionally "safe" sectors behave like volatile stocks, and vice versa. This means sector alone doesn't fully capture trading behavior.
- These cross-sector groupings could be useful for portfolio construction, identifying stocks that diversify each other regardless of sector labels.

Limitations:

- K-Means assumes roughly spherical clusters of similar size, which may not hold for stock data.
- We used only four aggregate features. Adding more (e.g., autocorrelation, max drawdown) could reveal finer-grained groupings.

Summary

Problem	Algorithm	Key Metric	Result	Takeaway
Classification	Random Forest	Accuracy / AUC-ROC	~52% / ~0.52	Weak signal; stock direction is hard to predict from historical features alone
Regression	GBT	RMSE / R^2	~1.2% / ~0.0	Model can't beat naive mean prediction; daily returns have very low signal-to-noise
Clustering	K-Means	Silhouette	varies by K	Stocks naturally group by volatility/volume profile; partial sector alignment

Observations across all three tasks:

1. The classification and regression results are consistent: daily stock returns are largely unpredictable from the previous day's features. This aligns with what financial theory predicts for a well-functioning market.
2. The clustering task produced the most actionable insights because it doesn't try to predict the unpredictable. Instead, it reveals structural groupings that are useful for understanding which stocks behave similarly.
3. Hyperparameter tuning was performed for both RF (classification) and GBT (regression), as well as K selection for clustering. In all cases, the tuning produced modest improvements, confirming that model complexity isn't the bottleneck for the supervised tasks.

Task 2 — Data Analysis Objectives (30 pts)

Here we go through the 6 data analysis objectives we laid out in Phase 1. All the heavy lifting is done in Spark, and we pull small aggregated results into pandas for plotting.

Objective 1: Distribution of Daily Returns

We want to check if daily returns are actually normal or not. A lot of financial models assume they are, so if they're not, that changes how we should approach things.

In [17]:
```
# === Objective 1: Distribution of Daily Returns ===

# Compute summary statistics using Spark
return_stats = df.select(
    F.mean("daily_return").alias("mean"),
    F.stddev("daily_return").alias("std"),
    F.expr("percentile_approx(daily_return, 0.5)").alias("median"),
    F.skewness("daily_return").alias("skewness"),
    F.kurtosis("daily_return").alias("kurtosis"),
    F.min("daily_return").alias("min"),
    F.max("daily_return").alias("max"),
    F.count("daily_return").alias("n")
).collect()[0]

print("=== Daily Return Distribution Statistics (Spark) ===")
print(f"  N:         {return_stats['n']:,}")
print(f"  Mean:      {return_stats['mean']:.4f}%")
print(f"  Median:    {return_stats['median']:.4f}%")
print(f"  Std Dev:   {return_stats['std']:.4f}%")
print(f"  Skewness:  {return_stats['skewness']:.4f}")
print(f"  Kurtosis:  {return_stats['kurtosis']:.4f}  (normal = 0)")
print(f"  Min:       {return_stats['min']:.4f}%")
print(f"  Max:       {return_stats['max']:.4f}%")

# Collect returns for histogram (sampled for efficiency)
returns_pd = df.select("daily_return").sample(0.1, seed=42).toPandas()

fig, axes = plt.subplots(1, 3, figsize=(18, 5))

# Histogram with normal overlay
from scipy import stats as scipy_stats
x = np.linspace(returns_pd["daily_return"].min(), returns_pd["daily_return"]
normal_pdf = scipy_stats.norm.pdf(x, return_stats["mean"], return_stats["std

axes[0].hist(returns_pd["daily_return"], bins=120, density=True, alpha=0.7,
             color="steelblue", edgecolor="black", linewidth=0.3)
axes[0].plot(x, normal_pdf, "r-", linewidth=2, label="Normal fit")
```

```
axes[0].set_title("Daily Return Distribution vs Normal", fontsize=13)

=== Daily Return Distribution Statistics (Spark) ===
  N:          496,955
  Mean:       0.0304%
  Median:     0.0419%
  Std Dev:    1.2148%
  Skewness:   -0.0882
  Kurtosis:   1.1322  (normal = 0)
  Min:        -3.6800%
  Max:        3.5878%
```

```
Jarque-Bera test for normality:
  Statistic: 2715.11
  p-value:   0.00e+00
  Conclusion: Reject normality (p < 0.05)
```

What we found:

- Kurtosis is way above 0, so the distribution has fat tails — big moves happen more often than a normal distribution would suggest.
- There's a slight negative skew, meaning big drops are a bit more common than big gains.
- The QQ plot curves away from the line in both tails, and Jarque-Bera rejects normality easily.
- This backs up why we went with tree-based models (RF, GBT) instead of linear regression — they don't assume normality, so they handle these fat tails better.

Objective 2: Sector Performance

Do different sectors actually behave differently? If sectors have meaningfully different return/risk profiles, then sector is worth including as a feature.

In [18]:
```
# === Objective 2: Sector-Level Performance Comparison ===

sector_perf = df.filter(F.col("sector") != "Unknown").groupBy("sector").agg(
    F.mean("daily_return").alias("mean_return"),
    F.stddev("daily_return").alias("volatility"),
    F.mean("volume").alias("avg_volume"),
    F.mean("log_volume").alias("avg_log_volume"),
    F.count("*").alias("observations"),
    F.countDistinct("symbol").alias("num_stocks")
).orderBy("mean_return", ascending=False)

sector_pd = sector_perf.toPandas()

print("=== Sector Performance Summary ===")
print(sector_pd.to_string(index=False))

# Sharpe-like ratio (mean_return / volatility) - higher is better risk-adjus
sector_pd["sharpe_ratio"] = sector_pd["mean_return"] / sector_pd["volatility
sector_pd = sector_pd.sort_values("mean_return", ascending=True)

fig, axes = plt.subplots(1, 3, figsize=(18, 6))

# Mean return by sector
colors = ["green" if x >= 0 else "red" for x in sector_pd["mean_return"]]
axes[0].barh(sector_pd["sector"], sector_pd["mean_return"], color=colors, ec
axes[0].set_title("Mean Daily Return by Sector (%)", fontsize=13)
axes[0].set_xlabel("Mean Daily Return (%)")
axes[0].axvline(x=0, color="black", linewidth=0.5)

# Risk-return scatter
axes[1].scatter(sector_pd["volatility"], sector_pd["mean_return"],
                s=sector_pd["num_stocks"] * 8, alpha=0.7, edgecolors="black"
for _, row in sector_pd.iterrows():
    axes[1].annotate(row["sector"][:12], (row["volatility"], row["mean_retur
```

```
                        fontsize=7, ha="center", va="bottom")
axes[1].set_title("Risk vs Return by Sector", fontsize=13)
axes[1].set_xlabel("Volatility (Std of Daily Return %)")
axes[1].set_ylabel("Mean Daily Return (%)")
axes[1].axhline(y=0, color="gray", linestyle="--", linewidth=0.5)

# Sharpe-like ratio

14026            14
             Materials     0.013328    1.361570 3.569102e+06       14.345100
17102            17
                Energy     0.000997    1.469225 6.699273e+06       15.459536
16096            16
```

What we found:

- Yeah, sectors are pretty different. Tech and Health Care have higher average returns but also more volatility. Utilities and Consumer Staples are the boring-but-steady ones.
- When you adjust for risk (mean return / std), the rankings shift — some high-return sectors don't look as great once you factor in how much they bounce around.
- Energy had a rough time during 2014-2017 because of the oil price crash, which shows up clearly here.
- Bottom line: sector carries real information and is worth using as a feature in both classification and clustering.

Objective 3: Temporal Patterns

Are there calendar effects? Like do stocks do worse on Mondays or better in January? These are well-known phenomena in finance ("Monday effect", "January effect") and if they show up in our data, the temporal features we engineered are justified.

In [19]:
```
# === Objective 3: Temporal Patterns ===

# --- Day of Week ---
dow_stats = df.groupBy("day_of_week").agg(
    F.mean("daily_return").alias("mean_return"),
    F.stddev("daily_return").alias("volatility"),
    F.mean("volume").alias("avg_volume"),
    F.count("*").alias("n")
).orderBy("day_of_week").toPandas()
dow_labels = ["Mon", "Tue", "Wed", "Thu", "Fri"]
dow_stats["day_name"] = dow_labels

# --- Month ---
month_stats = df.groupBy("month").agg(
    F.mean("daily_return").alias("mean_return"),
    F.stddev("daily_return").alias("volatility"),
    F.count("*").alias("n")
).orderBy("month").toPandas()
month_labels = ["Jan","Feb","Mar","Apr","May","Jun","Jul","Aug","Sep","Oct",
month_stats["month_name"] = month_labels

# --- Year ---
year_stats = df.groupBy("year").agg(
    F.mean("daily_return").alias("mean_return"),
    F.stddev("daily_return").alias("volatility"),
    F.mean("volume").alias("avg_volume"),
    F.count("*").alias("n")
).orderBy("year").toPandas()

fig, axes = plt.subplots(2, 2, figsize=(15, 10))

# Day of week: return
colors_dow = ["green" if x >= 0 else "red" for x in dow_stats["mean_return"]
axes[0, 0].bar(dow_stats["day_name"], dow_stats["mean_return"], color=colors
```

```
                edgecolor="black", alpha=0.8)
axes[0, 0].axhline(y=0, color="black", linewidth=0.5)

 2017     0.023643    1.076928 3.970206e+06 126025
```

What we found:

- There are small differences by day of week — Monday tends to be slightly weaker, which is consistent with what finance literature says about the "Monday effect."
- Monthly patterns exist too. Some months like November and April tend to be positive, September tends to be weaker. Nothing huge though.
- Year-over-year, 2015 was the most volatile (China fears, August flash crash), while 2017 was calmer with steady gains.
- So including day_of_week and month as features makes sense. They don't carry a ton of signal, but there's something there.

Objective 4: Correlation Analysis

We need to figure out which features are basically saying the same thing (redundant) vs which ones carry different information. Feeding highly correlated inputs into a model is wasteful and can cause issues.

In [20]:
```
# === Objective 4: Correlation Analysis and Feature Selection ===

corr_cols = ["open", "high", "low", "close", "volume", "log_volume",
             "daily_return", "price_range", "prev_daily_return",
             "prev_price_range", "prev_log_volume", "prev_close"]

# Compute pairwise correlations using Spark
corr_data = {}
for col in corr_cols:
    row = {}
    for col2 in corr_cols:
        r = df.stat.corr(col, col2)
        row[col2] = round(r, 3)
    corr_data[col] = row

corr_matrix = pd.DataFrame(corr_data, index=corr_cols, columns=corr_cols)

fig, ax = plt.subplots(figsize=(14, 10))
import seaborn as sns
mask = np.triu(np.ones_like(corr_matrix, dtype=bool), k=1)
sns.heatmap(corr_matrix, annot=True, fmt=".2f", cmap="RdBu_r", center=0,
            square=True, mask=mask, ax=ax, annot_kws={"size": 8})
ax.set_title("Feature Correlation Matrix (computed in Spark)", fontsize=14)
plt.tight_layout()
plt.show()

# Highlight key findings
print("=== Key Correlation Findings ===")
print(f"  open  ↔ close:           {corr_matrix.loc['open','close']:.3f}  (r
print(f"  high  ↔ low:             {corr_matrix.loc['high','low']:.3f}  (nea
print(f"  volume ↔ close:          {corr_matrix.loc['volume','close']:.3f}
print(f"  daily_return ↔ prev_ret: {corr_matrix.loc['daily_return','prev_dai
print(f"  volume ↔ log_volume:     {corr_matrix.loc['volume','log_volume']:.
print(f"  price_range ↔ close:     {corr_matrix.loc['price_range','close']:.
```

```
=== Key Correlation Findings ===
  open  ↔ close:           1.000  (nearly identical — redundant)
  high  ↔ low:             1.000  (nearly identical — redundant)
  volume ↔ close:          -0.149  (low — independent info)
  daily_return ↔ prev_ret: -0.004  (weak — limited autocorrelation)
  volume ↔ log_volume:     0.678  (related but log reduces skew)
  price_range ↔ close:     0.780  (moderate — higher-priced stocks have wide
r ranges)
```

What we found:

- Open, high, low, close are all correlated above 0.99 with each other. No point using all four — we just use close (and prev_close for lagged features).
- Volume has low correlation with price, so it's adding different information. Good to keep.
- Daily return barely correlates with the previous day's return. This is actually the core problem — if there was strong autocorrelation, prediction would be much easier. The weak correlation explains why our classification and regression results are modest.
- price_range correlates with price level (expensive stocks like AMZN move more in dollar terms), which is expected.

- Our final feature set avoids redundancy while covering price, volume, momentum, sector, and time.

Objective 5: Volatility Ranking

Which stocks swing the most? Which are the calmest? This connects to clustering (do volatile stocks end up in the same cluster?) and also helps us understand if our models struggle more on volatile stocks.

In [21]:
```
# === Objective 5: Rank Stocks by Volatility ===

stock_vol = df.groupBy("symbol", "sector").agg(
    F.stddev("daily_return").alias("volatility"),
    F.mean("daily_return").alias("mean_return"),
    F.mean("volume").alias("avg_volume"),
    F.count("*").alias("trading_days")
).orderBy(F.desc("volatility"))

stock_vol_pd = stock_vol.toPandas()

# Top 15 and Bottom 15
top15 = stock_vol_pd.head(15)
bot15 = stock_vol_pd.tail(15).iloc[::-1]

fig, axes = plt.subplots(1, 2, figsize=(16, 7))

# Most volatile
axes[0].barh(range(len(top15)), top15["volatility"].values, color="salmon",
axes[0].set_yticks(range(len(top15)))
axes[0].set_yticklabels([f"{s} ({sec[:10]})" for s, sec in zip(top15["symbol
axes[0].set_title("Top 15 Most Volatile Stocks", fontsize=13)
axes[0].set_xlabel("Volatility (Std of Daily Return %)")
axes[0].invert_yaxis()

# Least volatile
axes[1].barh(range(len(bot15)), bot15["volatility"].values, color="lightgree
axes[1].set_yticks(range(len(bot15)))
axes[1].set_yticklabels([f"{s} ({sec[:10]})" for s, sec in zip(bot15["symbol
axes[1].set_title("Top 15 Least Volatile Stocks", fontsize=13)
axes[1].set_xlabel("Volatility (Std of Daily Return %)")
axes[1].invert_yaxis()

plt.tight_layout()
plt.show()

# Volatility distribution
fig2, axes2 = plt.subplots(1, 2, figsize=(14, 5))

axes2[0].hist(stock_vol_pd["volatility"], bins=40, edgecolor="black", alpha=
axes2[0].set_title("Distribution of Stock-Level Volatility", fontsize=13)
axes2[0].set_xlabel("Volatility (Std of Daily Return %)")
axes2[0].set_ylabel("Number of Stocks")
```

```
axes2[0].axvline(x=stock_vol_pd["volatility"].median(), color="red", linesty
                 label=f'Median: {stock_vol_pd["volatility"].median():.2f}%'
axes2[0].legend()

# Volatility by sector (box plot)
sector_groups = stock_vol_pd[stock_vol_pd["sector"] != "Unknown"]
sectors_ordered = sector_groups.groupby("sector")["volatility"].median().sor
data_boxes = [sector_groups[sector_groups["sector"] == s]["volatility"].valu
bp = axes2[1].boxplot(data_boxes, vert=True, patch_artist=True,
                      labels=[s[:12] for s in sectors_ordered])
for patch in bp["boxes"]:
    patch.set_facecolor("lightblue")
axes2[1].set_title("Volatility Distribution by Sector", fontsize=13)
axes2[1].set_ylabel("Volatility (%)")
axes2[1].tick_params(axis="x", rotation=45)

plt.tight_layout()
plt.show()

print("=== Volatility Summary Statistics ===")
print(f"  Mean:   {stock_vol_pd['volatility'].mean():.4f}%")
print(f"  Median: {stock_vol_pd['volatility'].median():.4f}%")
print(f"  Std:    {stock_vol_pd['volatility'].std():.4f}%")
print(f"  Range:  {stock_vol_pd['volatility'].min():.4f}% — {stock_vol_pd['v
```

```
=== Volatility Summary Statistics ===
  Mean:   1.1862%
  Median: 1.1336%
  Std:    0.2733%
  Range:  0.6972% – 2.3456%
```

What we found:

- There's a huge range — the most volatile stocks have 3-4x the daily return standard deviation compared to the calmest ones.
- High-volatility stocks tend to be in Energy, Biotech, and some Consumer Discretionary names. Low-volatility ones are mostly Utilities and Consumer Staples, which makes intuitive sense.
- The distribution is right-skewed — most stocks have moderate volatility, but there's a long tail of really jumpy ones.
- Looking at the box plots, Energy and Health Care have the widest spread *within* the sector, meaning not all stocks in those sectors behave the same.
- This ties into our clustering results — volatility ended up being the main thing that separated the clusters, even more than sector did.

Objective 6: Volume Spikes and Market Events

Do big volume days line up with actual market events? And does high volume tell us anything about returns?

In [22]:
```
# === Objective 6: Volume Spikes and Market Events ===

# Aggregate daily total volume and mean return across all stocks
daily_agg = df.groupBy("date").agg(
    F.sum("volume").alias("total_volume"),
    F.mean("daily_return").alias("mean_return"),
    F.stddev("daily_return").alias("return_std"),
    F.count("*").alias("n_stocks")
).orderBy("date")

daily_pd = daily_agg.toPandas()
daily_pd["date"] = pd.to_datetime(daily_pd["date"])

# Compute rolling 20-day average volume to identify spikes
daily_pd["vol_ma20"] = daily_pd["total_volume"].rolling(20, center=False).me
daily_pd["vol_ratio"] = daily_pd["total_volume"] / daily_pd["vol_ma20"]

# Identify top spike days (volume > 1.5x the 20-day average)
spikes = daily_pd[daily_pd["vol_ratio"] > 1.5].sort_values("vol_ratio", asce

```

What we found:

- The volume spikes are clearly tied to real events. August 2015 flash crash (China fears), Brexit in June 2016, Trump's election in November 2016 — all show up as obvious spikes.
- High volume days tend to also be high absolute-return days. When the market is really moving, everyone is trading.
- The top 10 highest-volume days basically all correspond to days with big market moves, either up or down.
- There's also a slight downward trend in overall volume over 2014-2017, probably due to more algorithmic trading with smaller orders.
- Volume doesn't predict direction, but it does signal when the market is in a volatile state. A "volume surprise" feature (today's volume vs recent average) could potentially help flag unusual days.

Task 2 Summary

#	Objective	Main Finding	Why It Matters
1	Return distribution	Fat tails, not normal	Justifies tree-based models
2	Sector comparison	Different risk-return profiles	Sector is a useful feature
3	Temporal patterns	Weak but real calendar effects	day_of_week and month worth including
4	Correlations	OHLC redundant, volume independent	Guided our feature selection
5	Volatility ranking	Wide spread, partially by sector	Main clustering dimension
6	Volume spikes	Tied to market events	Volume signals regime changes

---

Personal Statements

Harshvardhan Shinde (hdshinde)

For Phase 2, I worked on the data analysis objectives, particularly looking into temporal patterns, sector comparisons, and how correlation analysis guided our feature selection. I also reviewed the ML model outputs and helped put together the final report. I confirm that this submission represents our team's own work.

Signature: Harshvardhan Shinde

Lorenzo Price (lorenzop)

I built the Spark ML pipeline for Phase 2 — the Random Forest classifier, GBT regressor, and K-Means clustering. I also set up the hyperparameter tuning with cross-validation, wrote the baseline comparison code for regression, and put together the presentation slides. This is our own work.

Signature: Lorenzo Price

Qiang Wu (qiangwu2)

I handled the report compilation for Phase 2, pulling together the ML results and data analysis into one document. I also did the return distribution analysis, volatility ranking, and the volume spike investigation. Everything here is our team's own work.
